This document offers detailed results from a number of robustness checks that were not included in the main text or in the online appendix. To maintain coherence, we have preserved the section numbering to align with the corresponding sections in the main article. Consequently, Section A.x.y complements Section x.y in the main text and so forth. For ease of reference, we also included a table of contents.

6. BASELINE PARAMETRIZATION AND ROBUSTNESS ANALYSIS

6.1. *Increasing the number of latent factors*

We augment the dimensionality by increasing the number of latent factors from 2 to 5 and proceed to examine the implications on our main outcomes of interest. Consistent with our earlier analytical framework and for the sake of maintaining comparability, we assume that the algorithm possesses a priori knowledge of the true number of latent factors. In appendix 10 we relax this assumption and allow the number of latent factors to be estimated through cross-validation.

With only two latent factors, it is easy to evenly position both products and consumers along the section of the unit circle located in the first orthant. In more than two dimensions, however, no general solution is known for the same problem, and one needs to resort to some kind of approximation. In this paper, we position 801 products and 24030 consumers on the surface \mathcal{S} of the positive half-segment of the 5-dimensional hypersphere in the following way. We first generated a large number R of random uniformly distributed points on \mathcal{S} , and grouped them in G subsets using the k-means algorithm, a well-known clustering technique. This iterative algorithm aims at minimizing the ratio of the total variance within the subsets and the total variance between them. Upon convergence, the algorithm delivers G points on \mathcal{S} , the “centroids” of each subset, whose coordinates are the averages of the coordinates of the point in the same subset (normalized so that they belong to \mathcal{S}). Our implementation of the k-means approach pre-selects G_0 centroids, and lets the algorithm determine the position of the remaining $G - G_0$. The products’ position is determined in two steps. In the first, we set $G_0 = 6$, fixing the central product (located at $(\sqrt{5})^{-1}$) and the 5 products situated at the corners of \mathcal{S} , and find the position of $G - G_0 = 19 - 6 = 13$ additional products; this delivers $m_{\mathcal{M}} = 19$ approximately evenly spaced points on \mathcal{S} , while keeping the central and the corner products. In the second step, we fix the $G_0 = 19$ points obtained in the first step and let the algorithm determine the position of the remaining $G - G_0 = 801 - 19 = 782$. Finally, consumers are positioned in groups of $24030/801 = 30$ at the same point as the products. The k-means algorithm is only guaranteed to converge to a local minimum. To avoid spurious solutions, we tried 10^6 random initial allocations of the R points to G groups and we picked the final allocation that minimizes the random search benchmark’s HHI index at zero prices. We also experimented with this approach in two dimensions, obtaining a products’ positioning very close to the optimal deterministic one.

Table 1 shows that when prices are set to zero, market concentration significantly increases. However, this increase is limited compared to the baseline case with two factors ($H = 2$). In Table 2, we confirm that equilibrium prices also rise relative to the benchmark. This price increase is significantly larger than that of the baseline case and thus has a larger impact on consumer surplus, as indicated in Table 3.

However, the effect of higher prices does not outweigh reduced search costs, leading to a positive impact on consumer surplus, though somewhat lower compared to the baseline for small values of α . We omit the analysis based on product location in this 5-dimensional extension product as user location changes from session to session and therefore averaging results across sessions is not useful.

6.2. Robustness checks

6.2.1. Density.

We report Herfindahl-Hirschman Index, equilibrium prices and equilibrium consumer surplus when we let the density d of the observe matrix $\tilde{\mathbf{R}}$ vary. In particular, we let d vary from 0.6% to 2.4% in increments of 0.3%.

TABLE 24. Equilibrium Consumer surplus ($d = 2.4\%$)

6.2.2. Number of consumers and products.

Another way to modify the amount of information is to change the numbers of consumers I and products J while keeping the density d fixed. We report four variations to the baseline specification. We begin by doubling and then halving the levels of I and J , all the while keeping their ratio I/J constant¹. The results are respectively in Tables 25, 26, 27 and Tables 28, 29, 30.

6.2.3. Reporting noise I: idiosyncratic shocks.

We study how changing the variance of the idiosyncratic shocks ϵ_{ij} affects the performance of the recommendation system. In the baseline, σ_ϵ was set at 20% of the expected utility across the J products. We now present estimates for the Herfindahl-Hirschman Index, the equilibrium prices and the equilibrium consumer surplus for σ_ϵ ranging from 0 to 40% of the aforementioned benchmark.

TABLE 114. Equilibrium Consumer Surplus ($\ell = 10$)

7. MARKET CONCENTRATION

7.5. *The feedback loop hypothesis*

As discussed in the main text, in our baseline analysis we abstract from the feedback loop effect extensively discussed in the computer science literature, which arises when the recommendations made by the RS generate the data that the system uses to make future recommendations. But what would be the impact of the feedback loop mechanism on our results?

To answer this question, we consider a different data-generating process. In the new process, the matrix $\tilde{\mathbf{R}}$ is filled in gradually, in a number of successive steps indexed by $\tau = 0, 1, 2, \dots$. Initially, $\tilde{\mathbf{R}}_0$ is the empty matrix; that is, a matrix with all entries missing. At step $\tau = 0$, each consumer then inspects a randomly drawn product resulting in ratings \tilde{u}_{ij} for the RS. The matrix $\tilde{\mathbf{R}}_1$ therefore has a density of $1/J$.

At each subsequent step $\tau \geq 1$, the RS uses $\tilde{\mathbf{R}}_\tau$ to estimate $\hat{\mathbf{R}}_\tau$ according to the estimation procedure described in section 2 and recommends to each consumer i the product with the highest rating:

$$j^*(i, \tau) = \arg \max_j \{\hat{r}_{ij\tau}\}. \tag{1}$$

This product is then tried by the consumer. Thus, $\tilde{\mathbf{R}}_{\tau+1}$ is obtained by adding to $\tilde{\mathbf{R}}_\tau$ one and only one entry $\tilde{u}_{ij^*(i,\tau)}$ for each of the I rows (i.e. for each consumer). If \tilde{u}_{ij} is not missing in $\tilde{\mathbf{R}}_\tau$, its value is overwritten. All other elements of $\tilde{\mathbf{R}}_\tau$ are unchanged. Thus, $\tilde{\mathbf{R}}_{\tau+1}$ is basically equal to $\tilde{\mathbf{R}}_\tau$ plus one new entry per consumer, which could be either a previous value overwritten or a brand new one.

As this process proceeds, the density of $\tilde{\mathbf{R}}_\tau$ increases. The algorithm’s learning phase ends when the matrix $\tilde{\mathbf{R}}_\tau$ achieves the same level of density d as in the baseline.³

We now investigate how the endogeneity of the data impacts our findings regarding market concentration, equilibrium prices, and consumer surplus. First, let us consider the case of subscription platforms, where the prices of individual products are set to zero. Table 115 shows that with endogenous data, RSs increase market concentration. The increase is smaller than in the baseline case when α is low, larger when α is high, but in any case the differences with the baseline case are modest.

TABLE 115. HHI with endogenous data and zero prices for different values of α .

³To achieve the target density level of $d = 1.2\%$, we need to assume that the algorithm operates in “exploration mode” during a certain percentage of the periods; otherwise, the process would get stuck in a steady state with a lower density. During exploration mode, the algorithm randomly recommends a product. An exploration rate of 10% is sufficient for our purposes. However, by adjusting the probability of exploration mode, we can create data that lie between purely exogenous and endogenous.

The analysis of the superstar effect and the reverse long-tail effect show a similar pattern: the effects of the RS identified in the baseline case are amplified when α is low, reduced when it is high.

TABLE 117. Market share of central product with endogenous data for different values of α .

As for the equilibrium prices, Table 118, confirms that they increase with the RS. Data endogeneity slightly reduces the price increase when α is low. The price increase is identical to the baseline case when α is high.

TABLE 118. Equilibrium prices with endogenous data, for different values of α .

The effect on the prices of individual products are also similar to that reported in the paper for the case of random data, as can be seen by comparing Figure 1 with Figure 5 in the main text.

FIGURE 1.—The prices of the different products ranked from 1 to 19 according to their location in the space of products: products 1 and 19 are peripheral, product 10 is central. The figure shows median, inter-quartile range (IQR), and the values obtained by subtracting 1.5 times the IQR range from the first quartile (Q1), and obtained by adding 1.5 times the IQR to the third quartile (Q3). That is the highest and lowest value excluding outliers.

Table 119 illustrates the impact of the RS on consumer surplus with endogenous data. Even though prices increase less than in the benchmark, consumer surplus is slightly lower (except for $\alpha = 0.25$). This is because the user/item pairs that the algorithm observes with endogenous data are somewhat correlated, which reduces the quality of the information available to the algorithm. This means that the precision of the estimates and the quality of the recommendations decrease compared to the case of completely random data.

TABLE 119. Consumer surplus net of search costs with equilibrium prices and endogenous data, for different values of α .

7.6. The uniformity effect

A noteworthy difference of endogeneity of the data is that the uniformity effect discussed in section 7.6 of the main text applies not only to consumers but also to products, as illustrates in Figure 2.

FIGURE 2.—Estimation biases (with $\alpha = 0$) with endogenous data: consumers (left) and products (right).

9. IMPACT OF INFORMATION ON PRICES AND SURPLUS

In order to gain further insights into the impact of information on prices, we conducted additional analyses by varying the parameter governing product differentiation levels and we present our result in Figure 3. These additional analyses confirm the significant role that information quality plays in price determination. The analysis consistently reaffirms that having more information leads to higher prices. The relationship between information and consumer

FIGURE 3.—Effect of more information

surplus continues to exhibit an inverted-U pattern, even when the value of α is positive but not excessively high. However, this pattern vanishes for non-small values of α .

10. ADDITIONAL ROBUSTNESS

10.1. *Estimating the number of latent factors*

In this exercise we let the algorithm autonomously estimate the number of latent factors H , which keeping the true number of factors equal to 2. The choice is made by means of a cross-validation procedure (see section A2 for a detailed description of the procedure). In this case, holding the true number of latent factors equal to $H = 2$, we let the algorithm choose the estimate \hat{H} from a grid 1, 2, 3, 4, 5. The cross-validation routine almost systematically identifies the correct number of factors, $H = 2$. In less than 5% of the cases, the algorithm chooses $\hat{H} = 3$ instead (see table 1 in section A2 for detail). In light of this, it is unsurprising that our findings remain mostly unchanged even when the algorithm independently determines the number of latent factors. The tables below substantiate this assertion for several selected exercises.

α	0	0.25	0.5	0.75	1
